Is education really underfunded in resource-rich economies? Evidence from a panel of U.S. states

Alexander James∗

January 30, 2015

Abstract

Existing development literature has argued that natural-resource endowments “curse” economic prosperity by reducing expenditures on education. According to this theory, public and private agents lack sufficient foresight to make optimal economic decisions and become poor as a result. Using a panel of U.S. state-level data, this paper offers evidence to the contrary. Public spending on education in resource-rich states greatly exceeds that in resource-scarce ones, and private education services are imperfectly crowded out as a result. More generally, this paper highlights the importance of exploiting both spatial and temporal variation in resource wealth when studying resource-rich economies.

Keywords: Natural Resources, Education, Public Policy, Resource Curse.

Children are our most valuable natural resource. Herbert Hoover.

1 Introduction

Natural resources play a critical (and often negative) role in the development process of poor and rich countries (Auty, 1990; Sachs and Warner, 1995, 1999, 2001; Mehlum, Moene and Ragnar, 2006; James and Aadland, 2010; Walker, 2013). A variety of mechanisms have been proposed (e.g., a Dutch Disease (Corden and Neary, 1982; Matsuyama, 1992), resource induced political corruption (Ross, 1999), civil conflict (Collier and Hoeffler, 1998), resource drag (Davis, 2011)). Yet another prominent theory posits that an abundance of natural resources induces slothful behavior and increases the opportunity cost of going to school, ultimately leading to a decline in the stock of human capital.

Analyzing a cross-section of countries, Gylfason (2001) documents a negative unconditional relationship between resource dependence and education expenditures and specifically argues that\(^1\):

\begin{quote}
Nations that are confident that their natural resources are their most important asset may inadvertently—and perhaps even deliberately!—neglect the development of their human resources, by devoting inadequate attention and expenditure to education. Their natural wealth may blind them to the need for educating their children.
\end{quote}

Other studies that have utilized sub-national data have provided a mixed bag of evidence. Using county-level data from the southern United States, Michaels (2011) finds some evidence that oil discoveries are associated with a more educated labor force in the long run (measured as the share of the population with a college degree). Black, McKinnish and Sanders (2005) study the Appalachian coal boom and find that high school enrollment rates in Kentucky and Pennsylvania declined in the 1970s and increased in the 1980s as the coal boom subsided.

Using a cross section of U.S. state-level data, Papyrakis and Gerlagh (2007) similarly document a negative and unconditional relationship between resource dependence and education expenditures. They specifically find that expenditures on education services expressed as a share of state GDP in 1986 are negatively correlated with a state’s level of resource dependence in the same year\(^2\). They go on to say that “The schooling variable has the most significant

---

\(^1\)See also Stijns (2005) who, using cross sections of international data, documents a negative relationship between resource dependence and education expenditures that is sensitive to the definition of resource dependence. Exploiting international data, Smith (2013) finds that resource discoveries are associated with increased education attainment but does not consider the effect of discoveries on education expenditures.

\(^2\)Papyrakis and Gerlagh define resource dependence as the share of a state’s primary sector (agriculture, forestry, fishing and mining) in state GDP.
relation to natural resource abundance at the 1% level, and resource abundance alone accounts for 17% of the variation in educational quality across different states.” Using education expenditures as a proxy for education quality, they conclude that natural resources—through their negative effect on education expenditures—account for about a quarter of the variation in growth across resource-poor and resource-rich U.S. states.

Such a finding suggests a lack of rationality and foresight on behalf economic agents and policy makers, significant institutional failures, or both. However, upon careful inspection, it is revealed that Papyrakis and Gerlagh failed to include the public sector in their analysis. Correcting for this apparent shortcoming, and exploiting both spatial and temporal variation in the data, paints natural resources—and resource-rich state governments—in a more favorable light. Using a panel of 48 U.S. states, spanning the years 1970-2008, I find that resource-rich governments spend more on education than their resource-scarce counterparts and private expenditures on education are imperfectly crowded out as a result. In fact, averaged from 1970 to 2008, total (private and public) per capita spending on education was about 6% higher in resource-rich states compared to resource-poor ones. This effect is more pronounced during periods in which the price of the resource is relatively high. For example, as a result of the energy-price boom of the early 1980s, in 1984 total education expenditures were 17% higher in resource-rich states than in resource-poor ones.

2 Identification Strategy

The identification consists of estimating two equations. The first is a difference-in-difference equation that controls for time-invariant unobserved characteristics like culture, political preferences and history. The second equation is essentially a repeated cross section. The difference-in-difference specification is given below:

\[
\ln\left( \frac{E_{i,t}}{\text{Pop}_{i,t}} \right) = \alpha + \sum_{t=1971}^{2008} \beta_{t,1}(Z_t \times D_i) + Z_t + S_i + \epsilon_{i,t,1},
\]

where \(Z_t\) and \(S_i\) are year and state fixed effects, respectively, and \(D_i\) is an indicator variable that defines whether or not a state is “resource rich”. In the following subsection, \(E_{i,t}\) will be defined as either private, public or total education expenditures and \(\text{Pop}_{i,t}\) is the population of state \(i\) at time \(t\). All prices are real and 2000 is the base year. \(\beta_{t,1}\) is interpreted as the treatment effect in year \(t\) (the effect of being a resource-rich state) relative to the treatment effect in 1970. A resource-rich state is either a top ten producer of oil or a top ten producer of natural gas. Rather than defining the treatment group using production data from a single year, average production levels were computed for each state. Natural gas production was
averaged from 1967 to 2008 and oil production was averaged from 1981 to 2008 (production data is constrained to that which is available from the Energy Information Administration). Therefore, top ten producers can be thought of as top ten “average” producers. There is significant overlap between those states that are top producers of oil and those that are top producers of gas such that there are twelve treatment states, not twenty. Those states are: Alabama, California, Colorado, Kansas, Louisiana, Missouri, North Dakota, New Mexico, Oklahoma, Texas, Utah and Wyoming. 

While equation (1) is estimated using fixed effects, remaining concerns of endogeneity are mitigated some by the treatment definition. While government and economic factors may affect energy production at the margin, top state energy producers are largely defined by geology. New Hampshire, for example, is not a top-ten producer of energy, and there is little the state government of New Hampshire can do to change this.

The estimation of equation (1) describes how the relative treatment effect changes over time. It does not reveal, however, any information about how much resource-rich states spend on education relative to resource-poor ones. In light of this, a variant of equation (1) is estimated that does not include state fixed effects and the treatment effect is estimated for all years, 1970 to 2008. Specifically, variations of the following equation are estimated:

\[
\ln\left(\frac{E_{i,t}}{\text{Pop}_{i,t}}\right) = \alpha + \sum_{t=1970}^{2008} \beta_{t,2}(Z_t \times D_i) + Z_t + \epsilon_{i,t,2}.
\]

(2)

By omitting state fixed effects from equation (2), \(\beta_{t,2}\) describes the treatment effect in year \(t\), and is estimated for all years, 1970-2008. The important difference between equation (1) and (2) is that the treatment effect in equation (1) is expressed relative to the treatment effect in the base year, 1970.

3 Data

Following Papyrakis and Gerlagh, private education expenditures are defined as “education services”. The BEA reports this data as a sub-category of “Private, Non Farm Earnings” and specifically defines education services as “establishments that provide instruction and training in a wide variety of subjects. This instruction and training is provided by specialized establishments, such as schools, colleges, universities, and training centers.” The definition

---

3Alternatively, one could define a resource-rich state as being a top ten producer of energy (oil and gas) per capita and then averaging over this metric. Doing so, treatment states are: Texas, Wyoming, North Dakota, Colorado, Louisiana, Kansas, Montana, Utah, New Mexico and Oklahoma. Using this alternative definition of treatment states does not change any of the results in a meaningful way.
goes on to read that, “BEA reports only private schools in its education services industry
corresponding to NAICS code 61...”. This education services data is published by the BEA,
Regional Database and is available at bea.gov.

State-level public education expenditure data were collected from the Census Bureau,
Federal State & Local Government Database and is available at census.gov/govs/local. This
data describes total (elementary and higher education) state-level education expenditures and
does so going back to 1970. One benefit of such a long panel is that it allows the identification
to exploit both positive (approximately 1970 to 1980) and negative (approximately 1980 to
1990) variation in resource production. This permits the analysis to say something meaningful
about potential asymmetry in the government response to positive and negative resource
shocks.

Total education expenditures are defined as the sum of private and public education
expenditures. State expenditures make up the large majority of total education spending. In
fact, averaged across all U.S. states, in 2008, state spending was more than 80% of total edu-
cation spending. As will be discussed in the next section, a larger share of education spending
is public in resource-rich states—especially when the price of the resource is relatively high.
For example, in 1984 (the cusp of the energy price boom of the early 1980s), nearly 98% of
education expenditures in Wyoming came from the state. Similar figures are found when
looking at other states as well (e.g., North Dakota and New Mexico).

Oil and gas production data were collected from the Energy Information Administration
(EIA) and is available at eia.gov. This is also the source for energy price data that was
used to construct Figure 1, which provides a graphical description of the value of oil and gas
production for the entire United States from 1970 to 2008.\footnote{The value of energy production
is the sum of the value of oil and gas production: oil production × oil price + gas production
× gas price. Nominal prices were converted to real ones using the CPI and 2000 is used as
the base year.}

4 Results

This section begins by reporting the results from the estimation of equation (1) having defined
$E_{i,t}$ as public education expenditures. The results are given in Figure 2a. Recall that for this
specification treatment effects are expressed relative to the treatment effect in 1970. The
relative treatment effect starts near zero and begins to increase almost immediately. However,
it does not become significant until around 1981. In 1984 it reaches a maximum of .13, implying
that public education spending per capita in treatment states was 13% higher than what it would have been without the energy price boom. After 1984, the treatment effect begins to fall and becomes insignificant in 1986 and remains so for the remainder of the period considered. It is interesting to note that the treatment effect begins to increase again around 2006, likely reflecting additional government revenue generated from hydraulic fracturing.

Figure 2b presents the results from the estimation of equation [2] where \( E_{i,t} \) is still defined as total public education expenditures. Recall that for this specification the treatment effect is not evaluated relative to the treatment effect in 1970 as it was in the previous specification. The annual treatment effect nonetheless follows a similar trend. It is similarly maximized in 1984, at which point the treatment effect is about .27, implying that in 1984 resource-rich state governments spent nearly 30% more on education per capita than resource-poor states did. Also note that, compared to the relative treatment effects, the annual treatment effects are shifted up by about 10% (significant at the 5% confidence level). In fact, the average annual treatment effect is .156, implying that, averaged from 1970 to 2008, resource-rich state governments spent about 15% more on education per capita than resource-poor state governments did.

Having established that public education is well funded in resource-rich states, I turn my attention to the private sector. The results from the estimation of equation [1] and [2] are given in Figures 3a and 3b, respectively. Discussing first the results from Figure 3a, the relative treatment effect is quite insignificant for all periods. There is some economically significant variation in the estimate though. For example, from around 1973 to 1986, the relative treatment effect decreased by about 10%. This may reflect within-state crowding out by public education expenditures.

Turning to the annual treatment effect (Figure 3b), private spending on education services is relatively low in resource-rich states and this is true for all years. Like the relative treatment effect, the annual treatment effect is quite stable but still varies in some economically significant ways. For example, similar to the relative treatment effect, from 1973 to 1986, the annual treatment effect decreased by 10%. The annual treatment effect nonetheless varies between -.4 and -.5, implying that on average, residents of resource-rich states privately spent 40% to 50% less on education per capita than those in resource-poor states, providing further evidence of a crowding out effect.

It may seem that, because private education expenditures in resource-poor states exceeds that in resource-rich ones by such a large margin (between 40% to 50%), total education expenditures would follow a similar trend. However, recall that private education expenditures make up a rather small share of total education spending (on average less than 20%). I formally test whether total education spending in resource-scarce states exceeds that in resource-poor
ones by re-estimating equations (1) and (2) defining $E_{i,t}$ as total (private and public) education expenditures. The results are given in Figures 4a and 4b. Starting with the results from the estimation of equation (1) and referencing Figure 4a, the relative treatment effect for total spending follows a similar trend as that for public education spending. This is unsurprising as there is little variation in the relative treatment effect for private spending (and hence variation in total spending is due to variation in public spending). The annual treatment effect (Figure 4b) is positive for most years (albeit only significantly so from around 1980 to 1986). Averaged across all years, the annual treatment effect is 6%, implying that on average, education spending per capita is about 6% higher in resource-rich states compared to resource-poor ones. Taken together, education appears to be relatively well funded in resource-rich states.

5 Conclusion

Existing development literature argues that natural resources may impede economic growth and development by reducing expenditures on education (Gylfason, 2001; Papyrakis and Geralgh, 2007). This paper builds upon this earlier work by considering the relationship between natural resources and total (private and public) education expenditures and further exploits both spatial and temporal variation in the data.

Contrary to existing conventional wisdom, natural resources fuel public expenditures on education and private expenditures are imperfectly crowded out as a result. Averaged from 1970 to 2008, total per capita education expenditures were about 6% greater in resource-rich states compared to resource-poor ones. And this effect is amplified during periods in which the price of energy is high. In 1984, for example, per capita public spending on education in resource-rich states was nearly 30% greater than in resource-poor ones. Applying this methodology—or a similar one that exploits both spatial and temporal data—to the international level may be a fruitful area of future research.
